Bacterial Diarrhea
Herbert L. DuPont, M.D.

A 47-year-old man reports a 1-week history of diarrhea, with grossly bloody stools for the past 5 days. He reports no history of travel, contacts with sick persons, or underlying gastrointestinal disease. How should he be evaluated and treated for an infectious cause of his illness?

Foodborne bacterial diarrhea is an emerging health threat that is attributable to the increased consumption of fresh vegetables and fruits, the challenges associated with producing large quantities of inexpensive foods, the increasing importation of foods from developing regions, and the growing pattern of consumption of foods in public restaurants.1 Of the more than 5.2 million cases of bacterial diarrhea that occur each year in the United States, 80% are a result of foodborne transmission.2 Person-to-person spread occurs if only a small amount of a pathogen is required for infection; these pathogens include shigella, Shiga toxin–producing Escherichia coli, and protozoal and viral agents.

Bacterial enteropathogens lead to an estimated 46,000 hospitalizations and 1500 deaths each year in the United States. The four most commonly reported bacterial enteropathogens in the United States — campylobacter, nontyphoid salmonella, Shiga toxin–producing E. coli, and shigella — are associated with an estimated cost of $7 billion annually.3 The first three of these organisms are spread to humans from animal reservoirs and are currently threatening our food supply.4 The highest incidence of campylobacter and salmonella infection occurs among infants, presumably because of cross-contamination in the household and the lower number of organisms required to cause clinical infection in infants than in older children and adults.

Table 1 lists the projected incidence of illness caused by bacterial enteropathogens in the United States and the typical clinical manifestations of these illnesses. In addition to these organisms, other bacterial enteropathogens cause variable numbers of cases of diarrhea. Aeromonas species occur worldwide but are particularly important in tropical regions; they cause acute or persistent diarrhea or dysenteric diarrhea (passage of grossly bloody stools). Plesiomonas shigelloides is a cause of acute diarrhea associated with seafood consumption and international travel. Enterotoxigenic E. coli is a growing cause of foodborne diarrhea, and enteroaggregative E. coli is an inadequately studied but potentially important cause of endemic diarrhea in children in the United States. Although bacterial enteropathogens are of the greatest importance for children living in the developing world, this article concentrates on bacterial diarrhea in the United States, which is similar to that in other industrialized regions. A previous review provides additional information about infectious diarrhea.6
noncholeraic vibrios, and noroviruses.

cases of diarrhea caused by salmonella and campylobacter when stools are cultured. In the evaluation of bloody diarrhea, the laboratory should further be instructed to look for Shiga toxin–producing E. coli. With seafood-associated diarrhea or dehydrating cholera-like diarrhea, the laboratory should be instructed to look for choleraic and noncholeraic vibrios. Indications for stool culture include the presence of severe diarrhea (passage of six or more unformed stools per day), diarrhea of any severity that persists for longer than a week, fever, dysentery, and multiple cases of illness that suggest an outbreak. Stool cultures are not routinely recommended in most cases of watery diarrhea or traveler’s diarrhea because of the low yield of bacterial pathogens. In most cases of infectious diarrhea, a single stool sample efficiently collected and studied by a competent laboratory is satisfactory for the work-up. When multiple stool samples are obtained from patients with diarrhea, the increased yield of bacterial pathogens is approximately 20% (one in five additional samples is positive).7 Pathogens associated with specific clinical syndromes are described below.

CONDITIONS ASSOCIATED WITH BACTERIAL DIARRHEA

Acute Watery Diarrhea

Most bacterial and nonbacterial enteropathogens produce acute watery diarrhea, so this condition is clinically nonspecific. The rate of underreporting of cases of acute watery diarrhea that are caused by detectable enteric pathogens, including most cases of diarrhea caused by salmonella and campylobacter, is substantial8; it is estimated that the cause is identified in fewer than 3% of cases in the United States. Compounding the problem of low rates of identification, many of the potentially important agents that cause watery diarrhea are not detectable by means of routine diagnostic laboratory tests; these agents include enterotoxigenic E. coli, enteraggregative E. coli, enteroinvasive E. coli, noncholeraic vibrios, and noroviruses.

The clinical manifestations of strains of diarrheogenic E. coli and diagnostic tests to detect them are summarized in Table 2. Specific strains of diarrheogenic E. coli are associated with characteristic clinical and epidemiologic features and distinct detection requirements. Thus, it is inappropriate to refer to E. coli diarrhea without considering the specific type. Molecular studies with the use of genome microarray analysis have helped to define the pangenomes of E. coli and offer insights into phylogenetic relationships.11

Dysentery

Passage of bloody stools suggests possible bacterial colitis. The four major causes of bloody diarrhea in the United States, in descending order of frequency of occurrence, are shigella, campylobacter, nontyphoid salmonella, and Shiga toxin–producing E. coli.12 Other organisms may also cause dysentery, including aeromonas species, noncholeraic vibrios, and Yersinia enterocolitica. It is estimated that only 5% of organisms that cause bloody diarrhea in the United States and that are detectable by laboratory tests are identified.2

Shiga toxin–producing E. coli strains cause watery diarrhea that becomes bloody in 1 to 5 days in 80% of patients; characteristic features of this condition include severe abdominal pain and cramps and passage of five or more unformed stools per 24 hours in the absence of fever.13 Infection by Shiga toxin–producing E. coli is the main cause of renal failure in childhood. In the hemolytic–uremic syndrome, Shiga toxin released in the gut enters the bloodstream and reaches the renal endothelium. Two thirds of children with the hemolytic–uremic syndrome require dialysis; the associated mortality rate is 3 to 5%. Although Shiga toxin–producing E. coli strains characteristically cause hemorrhagic colitis, manifestations of ischemic colitis may also occur.14

Approximately 40% of Shiga toxin–producing E. coli infections in the United States are non-O157 strains. Non-O157 Shiga toxin–producing E. coli can cause the same spectrum of disease as O157 strains. Unlike most O157:H7 strains, the non-O157 strains are usually sorbitol-fermenting. Strains of Shiga toxin–producing E. coli can be examined for the presence of Shiga toxin–carrying bacteriophages in their genome; these influence the spread of Shiga toxin genes.15 It appears that Shiga toxin 2 is more important in the pathogenesis of the hemolytic–uremic syndrome than

</table>
Shiga toxin 1. Laboratory evaluation of bloody stools should include assays for sorbitol-negative E. coli, followed by serotyping for O157:H7 strains, as well as examination for Shiga toxins 1 and 2 by means of commercial enzyme immunoassay. Shiga toxin 1 is positive but testing for sorbitol-negative E. coli (O157:H7) serotype is not necessary.

Food poisoning is the term used when a preformed toxin is ingested, resulting in infection rather than an enteric infection. Staphylococcus aureus causes vomiting within 2 to 7 hours after the ingestion of improperly cooked or stored food containing a heat-stable preformed toxin. Characteristic clinical manifestations; food may be cultured for staphylococcus or enzyme immunoassay may be performed for enterotoxin in food.

C. perfringens causes watery diarrhea without fever or vomiting; incubation period of 8–14 hr. Confirmed in foodborne outbreaks by detecting ≥10⁶ C. perfringens spores/g of feces in affected persons or ≥10⁵ organisms/g in food.

Bacillus cereus produces one of two toxins that may result in disease resembling that caused by S. aureus or C. perfringens, depending on the toxin produced. Most cases of food poisoning are of short duration, with recovery occurring in 1 to 2 days. Although it is possible to confirm the cause of food poisoning by microbiologic methods, these are rarely used, and the diagnosis is made in nearly all cases clinically without laboratory confirmation.

Shiga toxin 1. Food poisoning is the term used when a preformed toxin is ingested, resulting in infection rather than an enteric infection. Staphylococcus aureus causes vomiting within 2 to 7 hours after the ingestion of improperly cooked or stored food containing a heat-stable preformed toxin. Characteristic clinical manifestations; food may be cultured for staphylococcus or enzyme immunoassay may be performed for enterotoxin in food. Shiga toxin 1 is positive but testing for sorbitol-negative E. coli (O157:H7) serotype is not necessary.

In cases of commercial enzyme immunoassay 1 and 2 by means of commercial enzyme immunoassay.

<tr>
<td>Enteropathogenic E. coli</td>
<td>Typically belong to one of 17 serotypes, show attaching-and-effacing histopathological features, and have aggregation of polarized actin with pedestal formation at the site of attachment; virulence factors include plasmid-mediated bundle-forming pili that lead to focal attachment and the chromosomal <em>eae</em> gene encoding intimin, responsible for tight epithelial attachment and loss of microvilli; typically produce both bundle-forming pili and <em>eae</em>; atypical types produce <em>eae</em> but not bundle-forming pili.</td>
<td>Classic types cause hospital nursery outbreaks and pediatric diarrhea worldwide; atypical types may be more important causes of diarrhea in children and adults but remain largely unstudied in most populations.</td>
<td>Virulence assays have largely replaced serotyping, including demonstration of focal attachment to HEp-2 cells, DNA probe for enterohaemagglutinin factor, or PCR to identify bundle-forming pili and intimin.</td>
</tr>
<tr>
<td>Enterotoxigenic E. coli</td>
<td>Produce heat-labile cholera-like enterotoxin working through adenylate cyclase secretory pathways, a small-molecular-weight heat-stable enterotoxin working through guanylate cyclase secretory pathways, and colonization factor antigen gut-attachment fimbriae.</td>
<td>Important cause of pediatric diarrhea in the developing world; most important cause of traveler's diarrhea; becoming important as a foodborne pathogen in the United States.</td>
<td>Presence of a low-molecular-weight heat-stable enterotoxin, heat-labile cholera-like enterotoxin, or both by ELISA, DNA hybridization, traditional PCR, or real-time PCR.</td>
</tr>
<tr>
<td>Enteroinvasive E. coli</td>
<td>Presence of shigella-like invasion plasmid.</td>
<td>Common cause of acute shigella-like pediatric diarrhea in Brazil and eastern Europe; an occasional cause of sometimes large foodborne outbreaks in industrialized areas.</td>
<td>Presence of invasion plasmid of shigella by DNA probe or PCR; classically these strains have been identified by development of conjunctivitis when instilled into the eye of a guinea pig (Sereny test).</td>
</tr>
<tr>
<td>Shiga toxin–producing E. coli</td>
<td>Release Shiga toxin 1 and Shiga toxin 2, harbor locus of enterocyte effacement and type III secretion system inducing the attaching-and-effacing lesions characterized by accumulation of actin pedestals (as in enteropathogenic E. coli); absorbed Shiga toxins lead to development of the hemolytic–uremic syndrome, with rate increased by Shiga toxin–producing E. coli inoculum size, serotype of Shiga toxin–producing E. coli (O157 to non-O157 strains), organism virulence and Shiga toxin type (Shiga toxin 2 more than Shiga toxin 1), host age (increased rate among children and the elderly), immune status and immune response (activation of complement), and use of drugs (e.g., antibiotics, proton-pump inhibitors, and antimotility drugs).</td>
<td>Important cause of watery diarrhea, progressing to bloody diarrhea (hemorrhagic colitis) in 1–5 days affecting all age groups in industrialized regions; the hemolytic–uremic syndrome follows colitis in children (10% of cases) and the elderly (in &lt;1%) with 3–5% mortality; causes “ischemic colitis,” especially in the elderly.</td>
<td>Culture of a fecal sample on sorbitol–MacConkey media followed by testing sorbitol–nonfermenting E. coli for O157 and H7 lipopolysaccharides; in addition, the stool sample should be tested directly for Shiga toxin 1 and Shiga toxin 2 by enzyme immunoassay to improve the identification of O157 strains and to determine presence of non-O157 E. coli.</td>
</tr>
<tr>
<td>Enteraggregative E. coli</td>
<td>Strains harbor <em>aggR</em> regulon, encoding aggregative adherence fimbriae; strains heterogeneous and often possess other virulence factors (e.g., dispersin gene, Pic protease, pilin gene <em>aafA</em>, biofilm, cytotoxin proteins [Pet, EspP], and enterotoxins).</td>
<td>Important cause of diarrhea in children throughout the world, including the United States; organism associated with persistent pediatric diarrhea in developing regions; second most important cause of traveler's diarrhea; cause of AIDS-associated diarrhea.</td>
<td>Detected by characteristic attachment pattern to HEp-2 cells or by PCR based on detection of <em>aggR</em> regulatory gene or other defined virulence property.</td>
</tr>
<tr>
<td>Diffusely adherent E. coli</td>
<td>Show diffuse adherence to epithelial cells.</td>
<td>Cause of diarrhea in children older than 1 yr in developing countries and traveler's diarrhea.</td>
<td>Detected by characteristic attachment pattern in HEp-2 cells or by DNA probe or PCR for <em>Afa</em> and <em>Dr</em> genes.</td>
</tr>

</table>

*AIDS denotes acquired immunodeficiency syndrome, ELISA enzyme-linked immunosorbent assay, and PCR polymerase chain reaction.*
Patients with traveler’s diarrhea should be treated empirically with antibiotics without stool examination\textsuperscript{20} (Table 3). Antibiotics are also effective in prevention of the disease.\textsuperscript{23} When chemoprophylaxis is used, most authorities recommend rifaximin at a dose of 200 mg once or twice a day (with major meals) while the person is in an area of risk;\textsuperscript{23} an alternative regimen is two tablets (each tablet containing 262.5 mg) of bismuth subsalicylate with each meal and at bedtime (a total of eight tablets, or 2.1 g). In placebo-controlled trials involving U.S. students traveling in Mexico, the risk reduction in the development of traveler’s diarrhea with the use of prophylactic rifaximin treatment was approximately 70%, and with bismuth subsalicylate, the risk reduction was 65%.\textsuperscript{24} Indications for the use of chemoprophylaxis include an important trip (the purpose of which might be ruined by a short-term illness), underlying illness that might be worsened by diarrhea (e.g., congestive heart failure) or might make persons more susceptible to diarrhea (e.g., use of daily proton-pump inhibitor therapy), or cases in which previous bouts of traveler’s diarrhea suggest increased susceptibility to illness.\textsuperscript{25}

\textit{Nosocomial Diarrhea}

Diarrhea commonly occurs in the hospital, where patients (often with coexisting conditions) are receiving drugs and feedings and there is exposure to \textit{C. difficile} spores. Although \textit{C. difficile} accounts for a minority of antibiotic-associated and hospital-associated diarrhea, it should be considered in patients with clinically significant diarrhea (passage of three or more unformed stools per day), toxic dilatation of the colon or otherwise unexplained leukocytosis, or both. Patients with this infection often pass watery diarrhea stools but may also pass grossly bloody stools. \textit{C. difficile} diarrhea is increasing in frequency\textsuperscript{26} and is associated with an increasing mortality rate.\textsuperscript{27} Although \textit{C. difficile} diarrhea has been viewed as a nosocomial condition, it is increasingly being seen in the outpatient setting. Risk factors for \textit{C. difficile} diarrhea in the inpatient or outpatient setting include advanced age and coexisting conditions, alteration of intestinal flora by antimicrobial agents, and probably host genetics. The indigenous human intestinal microbiota is important to colonization resistance and recovery from antibiotic-associated and \textit{C. difficile} diarrhea.\textsuperscript{28} \textit{C. difficile} diarrhea was recently reviewed in the \textit{Journal}.\textsuperscript{29}

\begin{table}[h]
\centering
\begin{tabular}{|c|c|}
\hline
\textbf{TREATMENT} & \\
\hline
For all cases of diarrhea, attention to fluid and electrolyte replacement is fundamental. A diet of easily digestible food (such as tomato soup, chicken noodle soup, crackers, mashed potatoes, and boiled or baked vegetables and meats) or a “BRAT” (bananas, rice, applesauce, and toast) diet is often recommended for people with acute bacterial diarrhea, although randomized trials showing that these diets expedite recovery are lacking. Available data in children with acute diarrhea do support the continuation of oral feeding during the illness.\textsuperscript{30} Drugs to improve symptoms, particularly antimitotility drugs such as loperamide and diphenoxylate hydrochloride, can reduce the number of stools passed and may be useful in controlling the stool rate with watery diarrhea. They should not be used without concomitant antibacterial therapy in patients with fever or dysentery in whom the drug may lead to increased contact time of the enteropathogen with the gut mucosa; as long as appropriate antimicrobial therapy is given, there is no good evidence that antimitotility drugs are harmful in bacterial diarrhea.

Therapy with antimicrobial agents is important in most cases of diarrhea caused by invasive or inflammatory bacterial pathogens and is useful in other noninvasive forms of bacterial diarrhea. Table 3 provides recommendations for antibiotic therapy in each form of bacterial diarrhea.

Two bacterial organisms require special consideration with regard to recommended therapy. The first is acute diarrheal disease caused by nontyphoid salmonellosis. Bacteremia complicates the infection in approximately 8% of normal healthy persons. Patients with bacteremia often present with high fever and systemic toxic effects. Risk factors in the host that are associated with a higher than 8% risk of systemic salmonella infection during bouts of gastroenteritis include extremes of age (younger than 3 months and 65 years or older), corticosteroid use, inflammatory bowel disease, immunosuppression, hemoglobinopathy including most cases of sickle cell disease, and hemodialysis. People with one of these risk factors and nontyphoid salmonellosis should be treated with antibacterial drugs. Antibiotics should also be given to patients with intestinal salmonellosis and a known abdominal aneurysm or prosthetic heart valve to prevent establishment of a focal salmonella infection.

\end{tabular}
\end{table}
The second organism requiring special consideration is Shiga toxin–producing *Escherichia coli*. Some antibacterial drugs, including fluoroquinolones and trimethoprim–sulfamethoxazole, may increase the induction of phage-mediated production of Shiga toxin and theoretically could increase the risk of development of the hemolytic–uremic syndrome. However, an association between the use of these antibiotics and an increased risk of this syndrome has not been established, and other

* Multiple drugs are listed as alternatives for patients who may have an allergy to the primary drug. The doses given are derived from clinical trials, and they may not reflect doses for currently approved indications. Other drugs (not listed) may be appropriate for these conditions. Ceftriaxone is administered intravenously; the other listed drugs are given orally.
drugs, including fosfomycin, azithromycin, and rifaximin, do not appear to increase production of Shiga toxin. In a mouse model, azithromycin inhibited a Shiga toxin–induced inflammatory response and prevented death. Studies are needed to determine the effects of azithromycin and rifaximin on reducing diarrhea and decreasing the risk of the hemolytic–uremic syndrome among patients with Shiga toxin–producing E. coli infection. Pending such data, most authorities recommend supportive treatment only in patients with Shiga toxin–producing E. coli infection.

**Areas of Uncertainty**

Foodborne bacterial diarrhea continues to occur at a high rate in the United States and other industrialized areas. A newly established U.S. Food Safety Working Group has proposed increasing the number of food inspectors, modernizing federal laboratories, and updating regulatory laws controlling the food industry. In selected higher-risk foods (e.g., poultry), there may be a role for widespread food irradiation to reduce the risk of infection. Since most outbreaks (and many individual cases) are unrecognized, research is needed to identify improved methods of diagnosis and pathogen-reporting in patients with diarrheal disease.

Improved understanding is needed of factors that may influence susceptibility to bacterial diarrhea, including host genetics and the indigenous intestinal microbiota and associated colonization resistance. My colleagues and I have shown that genes encoding for inflammatory products are associated with susceptibility to a variety of types of bacterial diarrhea, including interleukin-8 and susceptibility to diarrhea due to enteraggregative E. coli or C. difficile; lactoferrin and osteoprotegerin (a cytokine belonging to a tumor necrosis factor receptor superfamily); and susceptibility to traveler’s diarrhea; and host interleukin-10 and susceptibility to enterotoxigenic E. coli diarrhea.

are uncertain. Table 4 reviews some potential complications, including the development of the Guillain–Barré syndrome (which has been recognized after campylobacter infection) and postinfectious irritable bowel syndrome (see Fig. 1 in the Supplementary Appendix, available with the full text of this article at NEJM.org).

GUIDELINES

The American College of Gastroenterology48 and the Infectious Diseases Society of America49 have provided recommendations regarding therapy for bacterial diarrhea. The current recommendations differ from the guidelines for bacterial enteric infection for which antimicrobial resistance has become widespread (e.g., trimethoprim–sulfamethoxazole has been replaced by one of the fluoroquinolones for many forms of bacterial diarrhea in adults).

CONCLUSIONS AND RECOMMENDATIONS

The differential diagnosis and evaluation for suspected bacterial diarrhea depend on the setting in which illness occurs and associated clinical features. A stool culture should be obtained from all patients with severe diarrhea when diarrhea is prolonged, when fever or dysentery complicates the illness, or when an outbreak has occurred. A single examination of a diarrhea stool in a qualified laboratory is sufficient for the diagnosis of most cases of bacterial diarrhea. In patients with bloody diarrhea, such as the patient described in the vignette, fecal toxin assay by means of a commercial enzyme immunoassay is warranted in addition to stool culture. If testing for Shiga toxin is positive, the patient should receive supportive treatment but not antibiotic therapy, given the potential for some antibiotics to increase toxin production and the risk of the hemolytic–uremic syndrome. Antibiotic therapy is indicated for febrile dysentery that is not due to Shiga toxin–producing E. coli, moderate- to-severe cases of traveler’s diarrhea, and in patients with culture-proven bacterial diarrhea.

Supported by discretionary funds from the Kelsey Research Foundation and the University of Texas School of Public Health and in part by a grant from the National Institutes of Health (DK 56338) that funds the Texas Gulf Coast Digestive Diseases Center.

Dr. DuPont reports receiving consulting fees, lecture fees, and support from Salix Pharmaceuticals, consulting fees and grant support from McNeil Consumer Products, and grant support from Osel, Intercel, Optimer Pharmaceuticals, and Romark Laboratories, and serving as an expert witness for law firms representing parties in suits related to foodborne infection. No other potential conflict of interest relevant to the article was reported.
